

1 6.4.2.1 Disposal System Geometry

2 A single disposal system geometry is used in the BRAGFLO computational model (see
3 Appendix *PA, Section PA-4.2* BRAGFLO) with four different maps of material properties: one
4 for undisturbed conditions; one for the E1 intrusion event; ~~in which a borehole penetrates the~~
5 ~~panel and a Castile brine reservoir;~~ one for the E2 intrusion event, ~~in which a borehole penetrates~~
6 ~~the repository but not a Castile brine reservoir;~~ and one for the E1E2 intrusion event, ~~in which at~~
7 ~~least one E1 borehole and one other borehole penetrate a disposal panel~~ (see Section 6.4.13.5).
8 The geometry and material maps used in BRAGFLO are similar; each is a model for fluid flow
9 calculations that represents the three-dimensional physical system in a two-dimensional plane
10 ~~that cuts~~ *cutting* vertically through the repository and surrounding strata. Side views of the
11 vertical cross section and two of the material maps are presented in Figures ~~6-136-14~~ and ~~6-146-~~
12 ~~15~~. In these figures, the boundaries of grid blocks discretized in the model (see Appendix
13 BRAGFLO, Section 4.5, for details of the finite-difference method) are shown with dashed lines;
14 each grid block is associated with material properties representing an important feature of the
15 disposal system. These associations between grid blocks and material properties are shown by
16 color and number in the figures. The two figures differ in that the material property map used
17 for E1 intrusion events (Figure ~~6-146-15~~) includes a material region representing the borehole
18 (*Column 26 Region 1*) that is not present in the undisturbed case (*Figure 6-14*). The borehole
19 region vertically transects other material regions and connects the single panel (*Rows 10, 11, and*
20 *12 Region 23*) with the Castile brine reservoir (*Rows 1 and 2 Region 30*), marker beds, overlying
21 units, and the surface. The E2 intrusion event material regions are similar to those of E1, except
22 that the modeled borehole region does not extend below the repository and therefore does not
23 contact a brine reservoir. ~~Additionally, the extent of the Castile brine reservoir is different from~~
24 ~~undisturbed to disturbed performance. This difference has no impact on results because no~~
25 ~~natural FEPs are retained that can create a pathway from the Castile to the repository.~~

26 Figures ~~6-136-14~~ and ~~6-146-15~~ show the relationship among material regions in the model and
27 how connections are made within the finite-difference scheme. However, by illustrating
28 equidimensional grid blocks, the volumetric relationship between grid blocks is greatly distorted.
29 To show the volumetric relationship among nodal blocks and between the repository and host
30 formations, a scaled side view of the vertical cross section used in BRAGFLO is shown in Figure
31 6-16. An undistorted 1:1 vertical:horizontal scale side view is in the upper left corner of Figure
32 6-16; at this scale, important model features are not resolvable. Therefore, two other views are
33 provided in which the vertical scale has been exaggerated 50:1 to show model features. Notice
34 that the modeling system extends ~~more than 15 miles (25 kilometers) to the north and 14 miles~~
35 ~~(22.45 km (14 mi))~~ *from the edge of the excavated repository in each direction, north and*
36 *south. The borehole is not centered; rather it is located 24.17 km from the north boundary*
37 *and 22.46 km from the south boundary.* ~~to the south from the borehole, which intersects the~~
38 ~~approximate center of the waste disposal region and includes the uppermost 2,990 feet (911~~
39 ~~meters) of rock at the WIPP site. Colors in Figure 6-14~~ *Figure 6-16 colors* are consistent with
40 colors for material regions in Figures ~~6-136-14~~ and ~~6-146-15~~.

41 Effects of flow in the third (out-of-plane) dimension are approximated with a two-dimensional
42 element configuration that simulates convergent or divergent flow to the north and south
43 centered on the repository in intact rocks laterally away from the repository. ~~A top-down (plan)~~
44 ~~view of the model is shown in Figure 6-16 and illustrates the discretization adopted to simulate~~

1 ~~convergent or divergent flow. Colors in Figure 6-16 are consistent with colors for material~~
 2 ~~regions in Figures 6-13 through 6-15 at the repository depth (node rows 8, 9, and 10). In this~~
 3 ~~text, the term width corresponds to the x (lateral) dimension of nodes, thickness refers to the y~~
 4 ~~(vertical) dimension, and depth refers to the z (out-of-plane) dimension. The effects of the grid~~
 5 ~~assumptions on fluid flow processes in the Salado are discussed in Appendix *PA, Attachment*~~
 6 ~~*MASS, Section 4.1.* MASS (Section MASS.4 and MASS Attachment 4-1)~~

7 Based on observations in the existing excavations, the DOE approximates the regionally variable
 8 dip in the Salado by incorporating a 1-degree dip to the south in the BRAGFLO computational
 9 mesh. This dip is not indicated in Figures ~~6-13~~~~6-14~~, ~~6-14~~~~6-15~~, and ~~6-15~~~~6-16~~.

10 The BRAGFLO definition of hydrostratigraphic units follows formation and member divisions.
 11 Inside the Salado, however, further subdivision of hydrostratigraphy has been made based on the
 12 observed ~~in~~ permeability differences between anhydrite-rich interbeds and halite-rich intervals.

13 This further subdivision has been made only at elevations near the repository horizon, because
 14 only in this region are such distinctions important. The models and assumptions ~~used to~~
 15 ~~representing~~ the various regions of material properties shown in Figures ~~6-13~~~~6-14~~ and ~~6-14~~~~6-15~~
 16 are discussed ~~beginning~~ in Section 6.4.3 and ~~in~~ Appendix *PA, Section 4.2.* ~~see MASS and PAR.~~
 17 The thickness of hydrostratigraphic units used in BRAGFLO are tabulated in Appendix ~~PAR,~~
 18 ~~*Attachment PAR, Table PAR-49.* (Table PAR-57).~~

19 6.4.2.2 Culebra Geometry

20 Although the BRAGFLO model contains a discretization of the Culebra and calculates flow
 21 there, the DOE uses a more detailed representation of ~~this unit~~ to estimate potential radionuclide
 22 releases to the accessible environment resulting from lateral subsurface transport *through the*
 23 *Culebra*. The conceptual model for flow and transport in this geometry is discussed in Section
 24 6.4.6.2. The boundary and initial conditions applied to this geometry are discussed in Section
 25 6.4.10.2. *MODFLOW-2000* ~~SECOFL2D~~ and ~~SECOTP2D~~ are the computer codes used to
 26 simulate groundwater flow and radionuclide transport in the Culebra. *The SECOFL2D code*
 27 *was used in the CCA to simulate groundwater flow and has been replaced with MODFLOW-*
 28 *2000. The groundwater flow and transport conceptual models have not changed; the*
 29 *implementation of the groundwater model has been updated.* The manner in which this
 30 geometry is linked to the BRAGFLO geometry described in the preceding section is discussed in
 31 Sections 6.4.6.2, 6.4.11, and Appendix *PA, Section 4.9.* ~~CODELINK (Section CODELINK-6).~~
 32 The grids used ~~for modeling~~ *to model* the Culebra are discussed in Section 6.4.6.2 *and Appendix*
 33 *PA, Section 4.8 (see also Appendix PA, Attachments MASS and TFIELD).*

34 6.4.3 *The Repository*

35 The repository, as shown in Figure 3-2 (see Chapter 3.0), is represented by *areas marked Waste*
 36 *Panel and rest of repository (RoR) north and south* Regions 23 to 27 in Figures ~~6-13~~~~6-14~~ and
 37 ~~6-14~~~~6-15~~. These regions include a waste disposal panel (Region 23), panel closures (Region 25
 38 *DRF_PCS, CONC_PCS, Anhydrite AB, and DRZ_PCS*), *two areas that represent the other*
 39 ~~panels and access drifts in the rest of the waste disposal region (Region 24~~ *RoR north and*

CCA-065-2

3
4 **Figure 6-16. A Top-Down View of a row of Elements in BRAGFLO Used for Undisturbed**
5 **Performance**

1 *south*), the operations region (~~Region 26~~ *Ops*), and the experimental region at the north end of
 2 the repository (~~Region 27~~ *Exp*). The shaft (~~Region 2~~ (which is further subdivided into *two*
 3 *primary regions marked Upper Shaft and Lower Shaft*) ~~Regions 3 through 11~~) intersects the
 4 repository between the operations region and the experimental region. The shaft is discussed in
 5 ~~detail in~~ Section 6.4.4. For human-intrusion events, the borehole (~~Region 1~~) intersects the waste
 6 disposal region in the *P* panel. In two-dimensional fluid flow codes, a grid block's length,
 7 volume, and cross-sectional area of faces connected to other grid blocks are important model
 8 features. For each region of the repository depicted, the BRAGFLO model geometry preserves
 9 the ~~true~~-excavated volume. Lateral dimensions have been determined to preserve volume and
 10 retain important cross-sectional areas and distances between defined regions, as discussed below.
 11 These simplifications are conservative with respect to fluid contact with waste, which is a critical
 12 factor in determining the quantity of actinides mobilized in the aqueous phase. The
 13 simplifications are conservative because (1) all pillars have been removed from the modeled
 14 panel, resulting in homogeneous waste regions through which fluid can flow directly; and (2) the
 15 panels in the rest of the repository *areas do not* have ~~neither pillars nor closures~~, resulting in a
 16 large homogeneous region that is assigned an average permeability within the range of *those*
 17 experimentally determined permeabilities (see Section 6.4.3.2 and *Appendix PA*, ~~Appendix~~
 18 *Attachment MASS Section 3.1* ~~MASS.5~~).

19 The single panel that is represented individually (~~Panel Region 23~~) is discretized to simulate
 20 radial flow to and from the borehole that intersects it. *In the CCA grid, the distance from the*
 21 *borehole to the shaft was 1260 m (4133.8 ft), the true distance from the shaft to the south end*
 22 *of the waste disposal region. In the current grid, the distance is 1097 m (3599 ft). The*
 23 *distance was reduced during the re-gridding process that accounted for the Option D panel*
 24 *closures and refinements to represent two RoRs (see Appendix PA, Attachment MASS, Section*
 25 *4.2.4). ~~The true distance from the south end of the waste disposal region to the waste handling~~
 26 ~~shaft is preserved in the model as the distance from the south end of the modeled panel to the~~
 27 ~~modeled single shaft.~~ In BRAGFLO, the single panel region is the southernmost portion of the
 28 repository. It occupies this position because separate modeling activities indicate that slightly
 29 larger releases may result from a panel in this position than from alternative placements (see
 30 Vaughn et al. 1995).*

31 *Panel closures were originally represented generically, since there were four options for the*
 32 *panel closure design. A condition of the original WIPP certification requires the DOE to use*
 33 *the Option D panel closure design constructed with Salado Mass Concrete (SMC). The*
 34 *closure representation for this analysis is modified in the models to better represent the*
 35 *Option D panel closures (see Appendix PA, Section 4.2.8, Attachment MASS, and Chapter*
 36 *9.0).* The panel-closure between the panel and the rest of the repository has a cross-sectional
 37 area equal to the cross-sectional area of the drifts between panels. The length and total volume
 38 of modeled panel closures is consistent with their *Option D* design. The panel closure between
 39 the rest of the repository and the operations regions has a cross-sectional area equal to the cross-
 40 sectional area of the drifts between the north end of the waste disposal region and the operations
 41 regions. Because there are two closures between the waste disposal region and the shafts in the
 42 operations regions, the modeled panel closures between the rest of the repository and the
 43 operations regions have a length and volume consistent with two panel closures.

1 A number of submodels have been defined within the repository region and are described in this
 2 section. The submodels that have been defined for repository processes are Creep Closure
 3 (6.4.3.1), Repository Fluid Flow (6.4.3.2), Gas Generation (6.4.3.3), Chemical Conditions in the
 4 Repository (6.4.3.4), Dissolved Actinide Source Term (6.4.3.5), and Source Term for Colloidal
 5 Actinides (6.4.3.6).

6 6.4.3.1 Creep Closure

7 Salt creep occurs naturally in the Salado halite in response to deviatoric stress. Inward creep of
 8 rock and the repository response is a process generally referred to as creep closure. Creep
 9 closure of excavated regions begins immediately because of excavation-induced deviatoric
 10 stress. If the rooms were empty, closure would proceed to the point where the void volume
 11 created by the excavation would be eliminated as the surrounding formation returns to a uniform
 12 stress state. In the waste disposal region, waste consolidation ~~will continue~~ until loading in the
 13 surrounding rock is uniform, at which point salt creep **and waste consolidation** ceases. The
 14 amount of waste consolidation that occurs and the time it takes to consolidate are governed by
 15 properties of the waste (waste strength, modulus, etc.), properties of the surrounding rock, the
 16 dimensions and location of the room, and the quantities of fluids present ~~in the room~~.

17 Fluids that could affect closure are brine that may enter the repository from the Salado or an
 18 intrusion borehole, air present in the repository when it is sealed, and gas produced by reactions
 19 occurring during waste degradation. Closure and consolidation can be slowed by fluid pressure
 20 in the repository. This can be quantified according to the principle of effective stress:

$$21 \quad \sigma_T = \sigma_e + p, \quad (6.11)$$

22 where σ_T is the stress caused by the weight of the overburden (an essentially constant value), p is
 23 the pressure of the repository pore fluid, and σ_e is the stress ~~that is~~ applied to the waste matrix.
 24 In this formulation, the waste is considered a skeleton structure containing pore fluids. As the
 25 pore pressure increases, an increasing amount of overburden stress is supported by pore fluid
 26 pressure, p , and less overburden stress is supported by the strength of the waste matrix. Waste
 27 consolidation will cease when the sum of the stresses felt by the waste matrix and fluid pressure
 28 reaches lithostatic pressure. If gas and brine quantities in the repository stabilize, creep closure
 29 will act to establish a constant pressure and pore volume.

30 In summary, creep closure of waste disposal areas will cause their volume to decrease as the
 31 Salado deforms to consolidate and encapsulate the waste, changing waste porosity and
 32 permeability. Resistance to creep closure will be caused by waste strength and fluid pressure.

33 Three major material-response models are required for closure analyses. The first model
 34 describes how the halite creeps as a function of time and stress. The second model describes the
 35 state of ~~consolidation of the waste~~ **consolidation** as a function of applied stress. A third
 36 constitutive model is used to model inelastic behavior of anhydrite marker beds (see Appendix
 37 **PA, Attachment MASS, Section 13.0** ~~PORSURE, PORSURE Attachment 1~~).

38 Halite deformation is predicted using a multimechanism deformation steady-state creep model
 39 with work hardening and recovery transient response. For the conditions of the WIPP, creep

1 mechanisms are governed by the temperature and shear stress at a given location in the
2 surroundings at any time. Although WIPP conditions are expected to be nearly isothermal at the
3 ambient natural underground temperature, several of the mechanisms can be active at the same
4 time because of the large range of stress states that occur around underground rooms and shafts.
5 The focus of the *model's* mechanistic part of the model is definition of steady-state creep strain,
6 with transient creep strain described through a multiplier on the steady-state rate, thus
7 accommodating both transient changes in stress loading and unloading.

8 The volumetric plasticity model is the mathematical model for room closure and waste
9 consolidation. The *model is discussed further and the* experimental data used in this model are
10 summarized and interpreted in *Butcher and Mendenhall (1992)*, Butcher et al. (1991, 65-76)
11 *and* Luker et al. (1991).

12 The volumetric plasticity model, multimechanism deformation model, and the inelastic
13 constitutive model for anhydrite were numerically implemented in the SANTOS computer code
14 to calculate the closure of disposal rooms for performance assessment *PA* (Appendix *PA*,
15 *Attachment PORSURF*. PORSURF, PORSURF Attachment 1). SANTOS is described in
16 Appendix PORSURF (Section PORSURF.3)

17 As a boundary condition, SANTOS requires estimates of the fluid pressure *estimates* and hence
18 the quantity of gas present in a disposal room. These estimates are obtained using the average
19 stoichiometry model of gas generation (Section 6.4.3.3) with different rates of gas generation
20 that reflect different assumptions about the quantity of brine that might be available in a waste
21 disposal room. The different rates of gas generation used in SANTOS bound the possible
22 conditions for gas content in the repository. With the volumetric plasticity model and the fluid
23 pressure boundary condition, SANTOS calculates the pore volume of the disposal room through
24 time.

25 In performance assessment *PA*, *SANTOS calculates* the time-dependent effects on volume *as a*
26 *result* of creep closure. calculated by SANTOS *These effects* are linked to the fluid-flow code
27 BRAGFLO by a porosity surface, which is a look-up table relating porosity (void volume) to (1)
28 time after sealing and (2) gas pressure. At the beginning of a time step, BRAGFLO evaluates the
29 pressure of a cell in the waste disposal regions; the pressure is sensitive to brine and gas flow and
30 the previous pore volume of the cell. The code then consults the porosity surface to find the
31 appropriate void volume of the cell for a given time and pressure. The void volume in the cell is
32 iteratively adjusted during a time step for consistency with gas generation, fluid movement, and
33 repository pressure. Additional details about the porosity surface method are included in
34 Appendix *PA, Attachment PORSURF*. BRAGFLO (Section 4.11) and Appendix PORSURF
35 (Sections PORSURF.1, PORSURF.2, and PORSURF Attachments 1 through 6). The porosity
36 surface method of incorporating the dynamic effect of creep closure *'s dynamic effect* in
37 performance assessment *PA* has been compared to more complex techniques that are
38 computationally impractical in a performance assessment *PA* (Freeze et al. 1995). In these
39 comparisons, the porosity surface method was found to be a reasonable representation of
40 *reasonably represent* behavior observed in more complex models.

41 The operations area and experimental area (*Columns 40 to 45* Regions 26 and 27 in Figures 6-14
42 and 6-15, respectively) are modeled as unfilled after closure in this performance assessment *PA*.

1 *The operations and experimental areas* These regions are expected to close in less than 200
2 years and do not require a porosity surface, in contrast to the region containing waste (Vaughn
3 et al. 1995). *These areas are assumed to be “pre-closed” and are assigned a constant low*
4 *porosity (18 percent) over the entire regulatory time frame.*

5 *Additional modeling confirmed that new waste types (compacted waste forms) and waste*
6 *containers (pipe overpacks) do not impact the adequacy of the original porosity surface*
7 *modeled in the CCA PA. The porosity surface used in the CCA is used in this analysis.*

8 6.4.3.2 Repository Fluid Flow

9 Fluid flow modeling within the repository is concerned with (1) fluid flow and distribution in the
10 waste, (2) fluid flow to and from the Salado and shafts, and (3) fluid flow between the repository
11 and intrusion boreholes. These are important in assessing gas generation rates (Section 6.4.3.3),
12 repository pressure, and the mobility of radionuclides in the disposal system. Additional
13 discussion of this topic is provided in *Appendix PA, Appendix, Section PA-4.2. MASS (Section*
14 *MASS.7).*

15 Disposal region fluid flow is affected by the geometrical association of pillars, rooms, drifts,
16 panel closures, possible borehole locations, the time-dependent properties of waste areas
17 resulting from creep closure, flow interactions with other parts of the disposal system, and
18 reactions that generate gas. As described in Section 6.4.3.1, creep closure changes disposal
19 region porosity. Depending on material properties and conditions, brine may flow into the
20 disposal region by moving down shafts and through the DRZ or operations region, or, during
21 disturbed conditions, through a borehole. Brine contained in the Salado may flow to the waste
22 disposal region because of pressure gradients created by the excavation. Brine flow into the
23 repository may be reduced as repository pressure increases, and brine may be expelled from the
24 repository if pressure in the repository exceeds brine pressure in the immediately surrounding
25 rock or borehole. Gas may be generated as waste decomposes, causing a pressure increase. Gas
26 may flow away from the waste *area to the anhydrite marker beds by hydrofracturing processes*
27 *in the DRZ and anhydrite interbeds.* into lower pressure areas, which may include disturbed
28 areas surrounding the repository, the interbeds, the shafts, or an intrusion borehole. Gas flow
29 into intact, halite-rich rock is not expected because of the expected high threshold pressure of
30 halite (see Section 6.4.5.1).

31 Fluid flow in the disposal system is conceptualized using principles of multiphase flow, except
32 for Culebra flow and transport modeling. In multiphase flow, a residual brine saturation (S_{br}), is
33 defined, which is the minimum saturation at which the brine phase has a nonzero relative
34 permeability; below this saturation, brine is immobile. In accordance with two-phase flow
35 theory, the residual gas saturation (S_{gr}) in the disposal system corresponds to the gas saturation
36 necessary to create an incipient gas-phase relative permeability; below this saturation, waste-
37 generated gas is immobile. The multiphase flow techniques adopted by the DOE are described
38 in *Appendix PA, Section 4.2 and Attachment MASS, Section 3.0. Appendix BRAGFLO*
39 *(Section 4.8).*

40 The intrinsic permeability of waste at a given time can influence repository system performance
41 by affecting the flow rate of gas or brine through the waste. Tests reported by Luker et al. (1991,

693-702) on simulated waste have shown material permeabilities ~~from about~~ *of* 10^{-12} to 10^{-16} m² on waste compacted under a lithostatic load. Performance assessment *PA* assigns a *waste* permeability ~~of the waste~~ as a constant at $2.4 \pm 7 \times 10^{-13}$ m² (Table ~~6-8~~ *Table 6-10*). This permeability value *was adopted from the value used in the PA verification test (EPA 1998, TSD V-B-14)*, is representative of the average value of compacted waste. Use of a constant value rather than a variable has been found acceptable (Vaughn et al. 1995).

Because two-phase relationships have not been measured for waste, performance assessment *PA* determines a range of possible two-phase conditions for the repository by applying the LHS technique to parameters within the Brooks-Corey two-phase equations. These and other parameters in the disposal room and repository flow model are shown in Tables ~~6-8~~ *6-10* and ~~6-9~~ *6-11*. Details about the two-phase equations and parameters used in performance assessment *PA* are included in Appendix *PA, Section 4.2; Attachment MASS, Section 3.0; BRAGFLO* (Sections 4.8 and 4.9) and *Attachment Appendix PAR* (Parameters 6 and 7).

Material properties in the waste are assumed to be homogeneous and are distributed in the BRAGFLO model in *to* cells whose volumes are much larger than an individual waste container.

Two processes that may occur on scales smaller than the cell volumes in BRAGFLO are wicking (the retention of brine in a capillary fringe) and puddling (the capture of brine in isolated pockets of waste caused by waste heterogeneity). Wicking is accounted for in the gas generation model (Section 6.4.3.3). Vaughn et al. (1995) found that puddling can be neglected.

The experimental and operations regions (*Columns 44 and 45 and 40 through 42, respectively, Regions 26 and 27* in Figures 6-14 and 6-15) are represented in performance assessment *PA* with a porosity of 18 percent and a permeability of 10^{-11} m² as a conservative upper bound. For postoperational performance, the panel closures (*Columns 31, 35, and 39* Region 25 in Figures 6-14 and 6-15) are represented with a porosity of *5* 7.5 percent and a *median* permeability of 1.78×10^{-19} 10^{-15} m², as discussed in Appendix *MASS* (*MASS Attachment 7-1*) *Appendix PA, Section 4.2, Attachment PAR, Parameter 10, and Attachment MASS, Section 19.0*.

6.4.3.3 Gas Generation

Gas will be produced in the repository ~~by~~ because of a variety of chemical reactions, primarily those occurring *among* between brine, metals, microbes, cellulose, and similar materials, plastics, and rubber materials, and ~~via liberation~~ *release* of the dissolved gases *produced by these reactions to the gaseous* to the gas phase. The dominant processes are anoxic corrosion of ~~metals~~ *steels and other Fe-based alloys* in the waste containers, and the waste and microbial *consumption* degradation of cellulose, plastics, and rubbers ~~materials~~ *in the waste*. Anoxic corrosion *of steels and other Fe-based alloys* reactions will occur between brine and steel, *and aluminum Al*, and aluminum *Al-base* alloys, *producing by water in the brine will occur, producing H₂*. Microbial *consumption* degradation of cellulose, *plastic, and rubber materials could* may produce a variety of gases; however, for the *current* waste inventory and expected conditions, CO₂ and CH₄ (methane) are expected to be the dominate *(as predicted at the time of the CCA)* gases for the process. Radiolysis has been *was* demonstrated by laboratory experiment and model calculations to be insignificant (see Appendix *MASS, Section MASS.8; Appendix PA, Attachment SCR, FEP W15 and W53*). Appendix *SCR, Section SCR.2.5.1.3*).

Table 6-106-8. Repository^{a1} and Panel Closures Parameter Values

Parameter (units)	Maximum	Minimum	Median or Constant
Permeability, k (square meters) – Waste Region	–	–	2.41 ⁷⁰ × 10 ⁻¹³
Permeability, k (square meters) – Operations and Experimental Regions	–	–	10 ⁻¹¹
Permeability (square meters) – Panel Closures	<i>1 × 10⁻¹⁷</i>	<i>2.00 × 10⁻²¹</i>	<i>1.78 × 10⁻¹⁹</i> 10⁻¹⁵
Initial Effective Porosity (percent) – Waste Region	–	–	84.8
Effective Porosity (percent) – Operations and Experimental Regions	–	–	18.0
Effective Porosity (percent) – Panel Closures	–	–	<i>5</i> 7.5
Threshold Pressure, P _t (pascals) – Repository ^{a1}	–	–	0
Threshold Pressure, P _t (pascals) – Panel Closures ^{b2}	–	–	<i>1.72 × 10⁶</i> 8.67 × 10⁴
Residual Brine Saturation, S _{br} (unitless) – Repository	0.552	0	0.276
Residual Brine Saturation, S _{br} (unitless) – Operations and Experimental Regions	–	–	0
Residual Brine Saturation, S _{br} (unitless) – Panel Closures	<i>0.60</i>	<i>0</i>	0.20
Residual Gas Saturation, S _{gr} (unitless) – Repository	0.15	0	0.075
Residual Gas Saturation, S _{gr} (unitless) – Operations and Experimental Regions	–	–	0
Residual Gas Saturation, S _{gr} (unitless) – Panel Closures	<i>0.40</i>	<i>0</i>	0.20
Pore Distribution Parameter, λ (unitless) – Repository	<i>5.78</i>	<i>1.44</i>	2.89
Pore Distribution Parameter, λ (unitless) – Operations and Experimental Regions	–	–	0.7
Pore Distribution Parameter, λ (unitless) – Panel Closures	<i>8.10</i>	<i>0.11</i>	0.94
Maximum Capillary Pressure (pascals) – Repository and Panel Closures	–	–	10 ⁸
Pore Compressibility (1/pascals) – Repository ^{c3}	–	–	0
Pore Compressibility (1/pascals) – Panel Closures	–	–	2.64 × 10⁻⁹ <i>6 × 10⁻¹¹</i>

^{a1} Unless specifically listed, Repository refers to operations, experimental, and waste regions.

^{b2} Threshold pressure (P_t) determined from the relationship: P_t = PCT_A · k^{PCT_EXP} where PCT_A and PCT_EXP are constants and k is the permeability.

^{c3} Accounted for in porosity surface.

1 Gas generation will affect repository pressure, which is important in other submodels of the
 2 disposal system, such as those calculating creep closure (Section 6.4.3.1), interbed fracturing
 3 (Section 6.4.5.2), two-phase flow (Section 6.4.3.2), and the radionuclide releases associated with
 4 spallings during an inadvertent drilling intrusion (Section 6.4.7). Thus, gas generation must be
 5 estimated in ~~performance assessment~~ *PA*.

Table 6-116-9. BRAGFLO Fluid Properties

Parameter (units)	Value
Reference Temperature (kelvin) ^{a 1}	300.15
Liquid Density (kilograms per cubic meter) ^{a,b 1,2} at	
Atmospheric Pressure	1,220.0
8 megapascals	1,223.0
15 megapascals	1,225.7
Liquid Viscosity (pascals * seconds) ^{b 2}	2.1×10^{-3}
Liquid Compressibility (1/pascals) ^{b 2}	3.1×10^{-10}
Gas Density (kilograms per cubic meter) ^{a,b 1,2} at:	
Atmospheric Pressure	0.0818
8 megapascals	6.17
15 megapascals	11.1
Gas Viscosity (pascals * seconds) ^{b 2}	8.93×10^{-6}

^{a 1} These values applied to fluids in all material regions in BRAGFLO.

^{b 2} See Appendix PA BRAGFLO (Section 4.24.4) for equations of state.

1 Performance assessment PA uses the average-stoichiometry model to estimate gas generation
 2 occurring in the waste-disposal region. This model was developed for WIPP performance
 3 assessment PA based on gas-generation experiments performed for the WIPP (see CCA
 4 Appendix MASS, Section MASS.8 and MASS Attachment 8-2). The average-stoichiometry
 5 model accounts for the formation of gas formed by anoxic corrosion of steels and other Fe-
 6 based alloys, and microbial consumption degradation of cellulose, including plastics, and
 7 rubbers materials. For the purpose of calculating repository pressure and gas flow, the density
 8 and viscosity of the generated gas are assumed to be those of H₂. In the average-stoichiometry
 9 model, gas is assumed to be generated at a rate dependent on the availability of brine in the
 10 computational cell. Gas can be generated by anoxic corrosion in all realizations, and is assumed
 11 to be generated by microbial activity degradation in half of the realizations. The average-
 12 stoichiometry model is based on experimental data on the rates of gas generation from anoxic
 13 corrosion of steels and microbial consumption degradation of papers under inundated and humid
 14 conditions. These data were used to develop ranges of possible gas-generation rates, as shown in
 15 Table 6-10 Table 6-12. In BRAGFLO, a gas-generation rate is determined from the rates listed
 16 in Table 6-10 Table 6-12 by a linear-interpolation method that combines humid and inundated
 17 rates based on the effective liquid saturation (Appendix PA BRAGFLO, Section PA-4.2.5 4.13).

18 The effective liquid saturation in a computational cell in of BRAGFLO for the purpose of gas
 19 generation is the computed liquid saturation in that cell plus an adjustment to account for
 20 uncertainty in the capillary rise (wicking) characteristics of the waste. Refer to Attachment PA,
 21 Sections PA-4.2.5 and PA-4.2.6 4.13 and 7.2.9, Attachment Appendices PAR (Parameter 8) and
 22 BRAGFLO for details on the treatment of wicking in the gas-generation model.

23 Anoxic corrosion is represented by a generic equation given in Appendix PA BRAGFLO
 24 (Section PA-4.2.4 4.13). This equation accounts for corrosion only for corrosion of the steels
 25 and other Fe-based alloys content in the repository by the reaction expected to dominate.

1 **Table 6-126-10. Average-Stoichiometry Gas Generation Model Parameter Values**

Parameter (units)	Maximum	Minimum	Median or Constant
Inundated Corrosion Rate for Steel without CO ₂ Present (meters per second)	3.17×10^{-14} 1.59 $\times 10^{-14}$	0	1.59 7.94 $\times 10^{-145}$
Humid Corrosion Rate for Steel	–	–	0
Probability of Microbial Degradation Consumption of Plastics and Rubbers Materials in the Waste in the Event of Significant Microbial Gas Generation (see Figure PAR-1) where 0 represents corrosion and no significant microbial gas generation. 1 represents cellulosic degradation only, and 2 represents cellulosic, plastic, and rubber degradation consumption	2	0	2
Rate for Microbial Degradation Activity Under Humid Conditions (mole per kilogram* second)	1.27×10^{-9}	0	6.34×10^{-10}
Rate for Microbial Degradation Activity under Brine-Inundated Conditions (mole per kilogram* second)	9.51×10^{-9}	3.17×10^{-10}	4.92×10^{-9}
Factor β for Microbial Reaction Rates (unitless)	1.0	0	0.5
Anoxic Corrosion Stoichiometric Factor X (unitless)	–	–	1.0
Average Density of Cellulosics Materials in CH-TRU Waste (kilograms per cubic meter)	–	–	58 54.0
Average Density of Cellulosics Materials in RH-TRU Waste (kilograms per cubic meter)	–	–	4.5 17.0
Average Density of Iron Steels and Other Fe-Based Materials Alloys in CH-TRU Waste (kilograms per cubic meter)	–	–	110.0 170.0
Average Density of Iron Steels and Other Fe-Based Materials Alloys in RH-TRU Waste (kilograms per cubic meter)	–	–	110.0 100.0
Average Density of Plastics Materials in CH-TRU Waste (kilograms per cubic meter)	–	–	42.0 34.0
Average Density of Plastics Materials in RH-TRU Waste (kilograms per cubic meter)	–	–	4.9 15.0
Average Density of Rubber Materials in CH-TRU Waste (kilograms per cubic meter)	–	–	14.0 10.0
Average Density of Rubber Materials in RH-TRU Waste (kilograms per cubic meter)	–	–	3.1 3.3
Bulk Density of Iron Steel Containers, CH-TRU Waste (kilograms per cubic meter)	–	–	170.0 139.0
Bulk Density of Iron Steel Containers, RH-TRU Waste (kilograms per cubic meter)	–	–	480.0 2.59 $\times 10^3$
Bulk Density of Plastic Liners, CH-TRU Waste (kilograms per cubic meter)	–	–	16.0 26.0
Bulk Density of Plastic Liners, RH-TRU Waste (kilograms per cubic meter)	–	–	1.4 3.1
Total Volume of CH-TRU Waste (cubic meters)	–	–	1.69×10^5
Total Volume of RH-TRU Waste (cubic meters)	–	–	7.08×10^3
Wicking Saturation (unitless)	1.0	0	0.5

1 Because the total quantity of ~~aluminum~~*Al* and ~~aluminum~~*Al-base* alloys is a small compared to
 2 the quantity of ~~iron~~*steels and other Fe-based metals*~~alloys~~, corrosion of ~~aluminum~~*Al* is omitted
 3 for simplicity. The ~~steels and other Fe-based alloys are~~ content of the repository is depleted
 4 separately in each computational cell (that is, a cell-by-cell basis), and gas generation can
 5 continue in cells, depending on parameter values, until all ~~the~~ *steels and other Fe-based alloys*
 6 ~~in a cell is~~*are* consumed. Brine in cells is consumed as gas generation proceeds. If a cell has a
 7 brine saturation equal to zero, it cannot produce gas by anoxic corrosion.

8 It is assumed ~~that there is no passivation of anoxic corrosion of~~ *steels or other Fe-based alloys*
 9 by CO₂ and H₂S produced by microbial ~~activity~~ *degradation* because microbial gas generation is
 10 too slow and also because CO₂ will be removed from the gaseous phase by ~~reaction with~~
 11 *reacting with* MgO ~~backfill~~. Details of the equations and parameter values are given *in*
 12 *Appendix PA, and Attachment PAR (Parameters 1 through 5) and Appendix BARRIERS.*
 13 ~~Appendix BRAGFLO (Section 4.13), Appendix PAR (Parameter 1), and Appendix MASS~~
 14 ~~(Section MASS.8.~~

15 Microbial ~~degradation~~ *activity* occurs in only half of the realizations because of uncertainties
 16 *associated with* in viability of the colonies *this process* (Appendix *PA, Attachment* MASS,
 17 Section MASS.8.0 and ~~MASS Attachment 8-2~~). Like anoxic corrosion, microbial ~~degradation~~
 18 *gas production* is represented by a generic equation, given ~~along with other details in~~ Appendix
 19 *PA BRAGFLO (Section 4.2.54.13)*. The cellulose inventory *of cellulosic, plastic, and rubber*
 20 *materials* is depleted on a cell-by-cell basis. Depending on parameter values, gas generation by
 21 microbial ~~degradation~~ *activity* can continue until all cellulose *materials* in the cell are
 22 degraded. Reaction with MgO ~~added to the repository~~ *the MgO engineered barrier* consumes
 23 CO₂ (see Section 6.4.3.4 and *Appendix PA, Attachment* Appendix SOTERM, Section
 24 *SOTERM.2.2.2*). Thus, the net quantity of gas ~~produced~~ *developed* by microbial ~~degradation~~
 25 *consumption of cellulosic, plastic, and rubber materials* is correlated with constituents of the
 26 waste disposal region. ~~Details are provided in Appendix BRAGFLO (Section 4.13).~~ It is
 27 assumed that microbial ~~degradation process~~ *activity* neither produces nor consumes water, but its
 28 rate is dependent on the amount of liquid present in a computational cell.

29 Microbial ~~degradation~~ may *also* consume plastic and rubber materials in the repository. The
 30 DOE assumes that in half of ~~those~~ *the* simulations in which ~~where~~ *microbial consumption*
 31 ~~degradation of cellulose~~ *materials* occurs, microbial ~~degradation~~ also ~~acts on~~ *consume*
 32 plastic and rubber materials in the waste-disposal region. As with cellulose *materials*, these
 33 *plastic and rubber* materials are depleted on a cell-by-cell basis. Parameter values for the
 34 average-stoichiometry model are summarized in ~~Table 6-10~~ *Table 6-12* and detailed in Appendix
 35 *PA, Attachment* PAR (Parameters 1 through 5).

36 6.4.3.4 Chemical Conditions in the Repository

37 The chemical conditions in the repository determine actinide solubility~~ies~~, a property *parameters*
 38 demonstrated in past analyses as important to disposal-system performance. In scenarios ~~that~~
 39 ~~have with~~ the potential to ~~result~~ *cause* in releases to the accessible environment, the DOE has
 40 determined that chemical conditions in the repository can be modeled *in PA as homogeneous*
 41 *throughout the waste-disposal area and constant (with the exception of brine content)*
 42 *throughout the 10,000-year regulatory period.* in performance assessment.—This use of

1 constant, *homogeneous* conditions is based on ~~an~~*the* assumption of equilibrium (for most
 2 processes) ~~between the~~*among* brine (*the composition of which is determined by the scenario*
 3 *being considered*), in the repository (determined by the scenario being considered), waste, MgO
 4 backfill, and abundant minerals *that are abundant in the Salado, the MgO engineered barrier,*
 5 *and the actinides in the waste*. Some exceptions to ~~the~~*this* equilibrium assumption of equilibria
 6 are present in some performance-assessment models and are discussed where appropriate. In
 7 addition to the following discussion, information supporting this position is presented in
 8 Appendix *PA, Attachments SOTERM and BARRIERS*.

9 Brine and waste within the WIPP repository are modeled as a ~~uniform~~*homogeneous* mixture of
 10 dissolved and solid-state species. Thermodynamic equilibrium is assumed for dissolved actinide
 11 concentrations, but oxidation-reduction reactions between the actinides and other waste
 12 components are not assumed to ~~proceed to~~ *reach* equilibrium. Although materials in the waste
 13 will actually dissolve at different rates, the *assumption of instantaneous solubility equilibria*
 14 *and* ~~presumption of homogeneity and solubility equilibrium~~, along with assumed disequilibrium
 15 ~~reduction-oxidation-~~*reduction* conditions, yields the largest reasonable concentration of aqueous
 16 *dissolved and colloidal* actinides in the repository. No chemical microenvironments that
 17 influence the overall chemical environment are expected to persist, nor is supersaturation
 18 expected during the 10,000-year regulatory period. The average temperature of the WIPP is
 19 expected to increase by less than ~~6~~*10°C from its ambient value of 28°C* as a result of radioactive
 20 decay and exothermic reactions, such as MgO hydration and carbonization, and the effect of this
 21 small increase is assumed negligible (see *Appendix PA, Attachment SCR, FEPs W72 and*
 22 *W73*). ~~Appendix WCA, Section WCA.5.3, and Appendix SCR, Sections SCR.2.2.2 and~~
 23 ~~SCR.2.5.7).~~

24 Brine composition in the repository can vary depending on the sequence of future human events.
 25 Calculating of brine mixing from different sources is not *feasible in* ~~amenable to~~ performance
 26 ~~assessment~~*PA*. The DOE has made the reasonable simplification that in the undisturbed
 27 performance and E2 scenarios, which do not include penetration of a Castile brine reservoir, all
 28 brine in the repository will have the composition of Salado brine (see *Appendix PA, Appendix*
 29 *Attachment SOTERM Section SOTERM.2.2.4*). In these scenarios, there is no process that
 30 could introduce Castile brine into the repository. For the E1 and E1E2 scenarios, which include
 31 penetration of a brine reservoir in the Castile, brine in the repository is assumed to have the
 32 composition of Castile brine at all times. Even though some Salado brine may enter the
 33 repository in these scenarios, it is reasonable to assume that Castile brine ~~is the dominant~~*es*
 34 ~~portion of brine~~ because the quantity of brine that can flow from a reservoir through a borehole
 35 and into the repository is substantial compared to the quantity of brine entering from the Salado.

36 The chemical environment in the repository after closure is expected to be *strongly* reducing
 37 (that is, lowered oxidation states are expected *for elements that can occur in more than one*
 38 *oxidation state* ~~to be favored~~). Any gaseous or dissolved oxygen present in the repository will
 39 be consumed quickly either by aerobic microbial *activity* or by oxic corrosion after repository
 40 closure. Moreover, the repository will contain large amounts of *metallic iron Fe*, and anoxic
 41 corrosion has been shown to produce considerable quantities of *hydrogen gas H₂*, and *Fe²⁺ Fe(II)*
 42 *oxides and hydroxides, and dissolved Fe(II) species* under expected repository conditions (see
 43 Appendix MASS, MASS Attachment 8-3 *of the CCA*). Despite the overall reducing conditions,
 44 however, a condition of ~~reduction-oxidation-~~*reduction* disequilibrium is assumed in that

1 ~~reduction-oxidation~~**reduction** reactions between dissolved actinides in possible oxidation states
2 are **not** assumed to ~~not~~ occur.

3 ~~Based on experimental data reported in Appendix SOTERM (Sections SOTERM.2.2.2,~~
4 ~~SOTERM.3.4, and SOTERM.3.6), the DOE has determined that alkaline conditions in the~~
5 ~~repository favor lower actinide solubility. As discussed in Section 3.3.3 and Appendix BACK~~
6 ~~MgO will be emplaced in the repository with the waste, in order to ensure alkaline conditions in~~
7 ~~the repository. MgO emplaced with the waste will react with the CO₂ that forms, creating~~
8 ~~magnesium carbonate minerals such as MgCO₃. The fugacity of CO₂ will be low and controlled~~
9 ~~by equilibrium considerations, rather than controlled by its rate of production by microbial~~
10 ~~degradation, because the DOE will emplace enough MgO with sufficient surface area to ensure~~
11 ~~CO₂ uptake will exceed the CO₂ production rate. Thus, by adding MgO to the repository, the~~
12 ~~DOE not only maintains alkaline conditions but also minimizes a property of the repository, its~~
13 ~~CO₂ fugacity, that would be expected to vary with time and potentially complicate the~~
14 ~~estimation of actinide solubilities in performance assessment.~~

15 MgO reacts with brine to form Mg(OH)₂. Mg(OH)₂ will react with CO₂ produced by the
16 microbial degradation of celluloses by reactions such as

18 There is a small amount of other alkaline components in the waste, such as Ca(OH)₂, contained
19 in the cementitious waste. Their effect will be minimal because they will be consumed by
20 reactions with MgCl₂ in the Salado brine and microbially generated CO₂. Details of those
21 buffering reactions are described in Appendix SOTERM (Section SOTERM.2.2.2).

22 Because the processes that might cause time dependent changes in important chemical
23 conditions in the repository have been eliminated by the addition of MgO and by the
24 assumptions made regarding brine composition, performance assessment uses constant chemical
25 conditions. The chemical conditions in the repository, including the pmH (the -log₁₀ of the
26 molality of the hydrogen ion), are assumed to be controlled by equilibrium between minerals
27 (that is, MgO, Salado halite, and anhydrite present in interbeds), brine present, and waste. In
28 Salado brine, the pmH in this system will be about 9.4. In Castile brine, the pmH in this system
29 will be about 9.9. In both systems, the carbon dioxide fugacity will be low and will be
30 determined by the equilibrium system (see Appendix SOTERM, Section SOTERM.2.2.2, for a
31 detailed discussion).

32 ***MgO in polypropylene “supersacks” is emplaced on top of the three-layer waste stacks to***
33 ***create conditions that reduce actinide solubilities in the repository (see Section 3.3.3;***
34 ***Appendix BARRIERS; and Appendix PA, Attachment SOTERM, Section SOTERM-2.0). If***
35 ***brine flows into the repository, MgO will react with water in brine and in the gaseous phase to***
36 ***produce brucite (Mg[OH]₂). MgO will react with essentially all of the CO₂ that could be***
37 ***produced by complete microbial consumption of the cellulosic, plastic, and rubber materials in***
38 ***the waste, and will create hydromagnesite with the composition Mg₅(CO₃)₄(OH)₂·4H₂O***
39 ***(Appendix BARRIERS; Appendix PA, Attachment SOTERM, Section 2). The most important***
40 ***MgO hydration and carbonation reactions that will occur in the WIPP are:***

In these equations, "aq or g" indicates that the H₂O or CO₂ that reacts with MgO and/or brucite could be present in the aqueous phase (brine) and/or the gaseous phase. The brucite-hydromagnesite carbonation reaction (6.13) will buffer (control) the fugacity (essentially the partial pressure) of CO₂ at a relatively low value of about 10^{-5.50} atm if significant microbial activity occurs. If microbial activity occurs, the predicted value of f_{CO₂} will be identical for both Salado and Castile brine. The brucite-hydromagnesite buffer will control f_{CO₂} effectively because: (1) the DOE is emplacing more than enough MgO to ensure the consumption of essentially all CO₂ that could be produced in the repository, and (2) the reactivity of the MgO being emplaced in the WIPP is such that its carbonation rate exceeds the CO₂ production rate. The brucite dissolution reaction

will buffer the pH at about 9 in both Salado and Castile brine if microbial activity occurs (see Appendix PA, Attachment SOTERM, Section 2). For the CRA-2004 PA vectors with microbial activity, the composition of Salado or Castile brine at equilibrium with major Salado minerals such as halite and anhydrite, the f_{CO₂} established by Reaction 13, and the pH established by Reaction 6.14, have been used to calculate actinide solubilities.

In the absence of microbial activity, the carbonation reaction

will buffer f_{CO₂} at 10^{-5.48} atm in Salado brine and at 10^{-6.15} atm in Castile brine. Reaction 6.14 will buffer the pH at about 9 in both Salado and Castile brine (see Appendix PA, Attachment SOTERM, Section 2). For the 2004 PA vectors without microbial activity, the composition of Salado or Castile brine at equilibrium with major Salado minerals, the f_{CO₂} established by Reaction 6.15, and the pH established by Reaction 6.14, have been used to calculate actinide solubilities.

There is a relatively small amount of portlandite Ca(OH)₂ associated with the Portland cement used to dewater process sludges. The quantity of portlandite is too small, however, to overcome the buffer capacity of the reactions described above.

An analysis was carried out to determine the MgO safety, defined by:

$$\text{MgO safety factor} = (\text{MgO}_{\text{emplaced}}) \div (\text{MgO}_{\text{required}}), \quad (6.16)$$

where MgO_{emplaced} is the quantity of MgO to be emplaced in the repository and MgO_{required} is the quantity of MgO required to consume the maximum amount of CO₂ produced by microbial consumption of all of the emplaced cellulosic, plastic, and rubber materials. This analysis used: (1) current estimates of the total quantities of cellulosic, plastic, rubber materials,

1 *nitrate (NO₃⁻), and sulfate (SO₄²⁻) in the TRU waste and waste containers present after closure*
2 *of the repository; and (2) recent results from a laboratory study of the efficacy of MgO. This*
3 *analysis yielded a MgO safety factor of 2.45 (Appendix BARRIERS, Section BARRIERS-2.0).*
4 *Therefore, there will be more than enough MgO to ensure that the conditions described above*
5 *will be established in the repository factor (see Appendix BARRIERS, Section BARRIERS-*
6 *2.0).*

7 The waste contains chemical compounds, known as organic ligands, that ~~can~~ *could* enhance the
8 concentration of actinide ions by forming soluble *dissolved* complexes of ~~with~~ these ions
9 *actinides and thus increase their solubilities*. The ligands of concern in the repository are
10 acetate, citrate, oxalate, and ethylenediaminetetraacetate (EDTA) because they are soluble in
11 brine and are known to be present in the waste (see WCA Section 8.11). *There are four organic*
12 *ligands of potential concern in the waste: acetate, citrate, ethylenediaminetetraacetic acid*
13 *(EDTA), and oxalate. These organic ligands could increase the solubilities of the actinides in*
14 *the waste because: (1) they are soluble in aqueous solutions such as WIPP brines, and*
15 *(2) they are known to form complexes with the actinides (see Appendix PA, Attachment*
16 *SOTERM, Section SOTERM-5.0) However, these organic ligands also bond strongly to other*
17 *metal species known to be in the repository system. The DOE assumes that because of this*
18 *competition effect, the organic ligands will have no significant impact on the repository*
19 *performance (see Appendix SOTERM, Section SOTERM.5, and Appendix SCR, Section*
20 *SCR.2.5.6, for discussion). Therefore, the effects of acetate, citrate, EDTA, and oxalate have*
21 *been included in the Fracture-Matrix Transport (FMT) calculations of actinide solubilities for*
22 *the CRA-2004 PA. These organic ligands will also form complexes with dissolved, cationic*
23 *species of several metals present in the repository. These metals will thus compete with the*
24 *actinides for the binding sites on these organic ligands. The effects of two of these metals,*
25 *Mg²⁺ and Ca²⁺, have been included in the solubility calculations for the CRA-2004 PA.*
26 *Including complexation of actinides and of Mg²⁺ and Ca²⁺ by acetate, citrate, EDTA, and*
27 *oxalate in the solubility calculations for the CRA-2004 PA has confirmed the conclusion in*
28 *the CCA that organics will not increase the solubilities of the actinides significantly (see CCA*
29 *Appendix SOTERM, Section SOTERM.5.0).*

30 6.4.3.5 Dissolved Actinide Source Term

31 Analysis reported in Appendix WCA (Section WCA.3) has demonstrated that the mobility in
32 brine of the following actinides may be significant in the performance assessment of the WIPP:
33 Th, U, Np, Pu, Cm, and Am. Although commonly referred to as actinides in the waste inventory,
34 these substances are almost always present in the waste as solid actinide oxides or solid actinide
35 salts, and if they dissolve in the WIPP brines, they will dissolve as complex ions. Additional
36 discussion of actinide solubility modeling and the oxidation state distribution of the actinides is
37 presented in Appendix SOTERM (Sections SOTERM.3 and SOTERM.4, respectively).

38 Actinides may be mobilized either by dissolution in brine as aqueous species, by
39 bioaccumulation or sorption onto colloidal particles, or by condensation into colloidal forms as
40 actinide-intrinsic colloids that could be carried by brine (see Section 6.4.3.6 for a discussion of
41 colloidal actinides). The dissolved actinide source term model calculates the dissolved
42 concentration of each actinide in solution by applying the modeled solubility for the particular
43 oxidation state, as determined by the oxidation state distribution for that actinide, at the

1 repository conditions presented in Section 6.4.3.4. Several oxidation states are not stable in the
2 chemically reducing conditions described in Section 6.4.3.4. The unstable oxidation states are
3 Np(VI), Pu(V), Pu(VI), and Am(V), as described in Appendix SOTERM (Section SOTERM.4).

4 Thorium will exist only in the IV oxidation state (see Appendix SOTERM, Section
5 SOTERM.4.1). Am and Cm will exist in only the III oxidation state (see Appendix SOTERM,
6 Sections SOTERM.4.4 and SOTERM.4.5). For the remaining actinides, Pu, U, and Np, it is
7 uncertain whether repository conditions will favor the lower or higher of the remaining oxidation
8 states (see Appendix SOTERM, Sections SOTERM.4.2, SOTERM.4.3, and SOTERM.4.6). The
9 DOE has captured the range of possible behavior by assuming that in half the realizations,
10 conditions within the repository are extremely reducing and the solubility of all three of these
11 actinides will be adequately represented by the solubility of their lower oxidation states. In the
12 other half of the realizations, the solubilities of these actinides are well represented by the
13 solubilities of the higher of the possible oxidation states. The factors controlling the aqueous
14 actinide concentration in a possible oxidation state are equilibrium with anhydrite, halite, MgO,
15 and brine.

16 The solubility of the actinides as a function of equilibrium between anhydrite, halite, MgO, and
17 brine is calculated outside of the performance assessment using FMT, a computer code for
18 calculating actinide concentration limits based on thermodynamic parameters. The parameters
19 for FMT are derived both from experimental investigations specifically designed to provide
20 parameter values for this model and from the published literature. FMT and its application are
21 described in Appendix SOTERM (Section SOTERM.3.5). Table 6-11 presents a summary of
22 solubility parameter values for each actinide oxidation state consistent with the assumptions
23 regarding chemical conditions stated in this section and Section 6.4.3.4. These values are
24 documented in Table 6-11 and in Appendix PAR (Parameters 36 through 45 and Table PAR-39).
25 Details of the generation of Table 6-11 are given in Appendix SOTERM (Section SOTERM.3).

26 *The actinide source term used in the CRA-2004 PA calculations represents the aqueous*
27 *concentrations of thorium (Th), uranium (U), Pu, and americium (Am) in the repository. The*
28 *source term is the sum of the dissolved species (solubility) and the mobile suspended*
29 *(colloidal) species of each of these actinides (see Section 6.4.3.6). The source term represents*
30 *the mobile concentrations of Th, U, Pu, and Am that could be released from the repository in*
31 *brine.*

32 *The actinide source term is limited to those radionuclides that could significantly affect the*
33 *long-term performance of the WIPP. These radionuclides are all isotopes of Th, U, Pu, and*
34 *Am. Their potential effects on the long-term performance of the repository can be ordered as*
35 *$Pu \approx Am \gg U > Th$ (Helton 1998). Other actinides, especially neptunium (Np), were included*
36 *in the laboratory and modeling studies used to develop the actinide source term because it was*
37 *not known which actinides could significantly affect the long-term performance of the*
38 *repository.*

39 *Although commonly referred to as “actinide,” these radioelements are almost always present*
40 *in the waste as solid actinide oxides or solid actinide salts and, if they dissolve in WIPP brines,*
41 *will form complex species (usually referred to as “complexes”) with nonradioactive, inorganic,*
42 *dissolved species such as carbonate ion (CO_3^{2-}), chloride ion (Cl) or hydroxide ion (OH), or*

Table 6-11. Summary of Dissolved Actinide Solubilities (moles per liter) in Castile and Salado Brines^a

Actinides	Brine	Maximum	Minimum	Median ^b or Constant
Am(III), Pu(III), Cm(III)	Salado	1.46×10^{-5}	5.82×10^{-9}	4.73×10^{-7}
Pu(IV), Th(IV), U(IV)	Salado	1.11×10^{-4}	4.40×10^{-8}	3.58×10^{-6}
Np(IV)	Salado	-	-	4.40×10^{-6}
Np(V)	Salado	-	-	2.30×10^{-6}
U(VI)	Salado	2.19×10^{-4}	8.70×10^{-8}	7.07×10^{-6}
Am(III), Pu(III), Cm(III)	Castile	1.64×10^{-6}	6.52×10^{-10}	5.30×10^{-8}
Pu(IV)	Castile	1.51×10^{-7}	6.00×10^{-11}	4.88×10^{-9}
Th(IV)	Castile	-	-	6.00×10^{-9}
U(IV)	Castile	-	-	6.00×10^{-9}
Np(IV)	Castile	-	-	6.00×10^{-9}
Np(V)	Castile	-	-	2.20×10^{-6}
U(VI)	Castile	2.21×10^{-4}	8.80×10^{-8}	7.15×10^{-6}

^a—Inorganic chemistry controlled by the $Mg(OH)_2$ – $MgCO_3$ pair.

^b—Appendix SOTERM (Sections SOTERM.3.6 and SOTERM.7.2) discusses the relationship of this distribution to the modeled solubility.

with nonradioactive, organic, dissolved species such as acetate, citrate, EDTA, or oxalate (see Section 6.4.3.4).

The postclosure chemical environment in the repository will be strongly reducing (see Section 6.4.3.4; Appendix PA, Attachment SOTERM, Section SOTERM-2.0). Previous studies of actinide chemistry imply that, under these conditions, Th will exist as Th(IV) (Appendix PA, Attachment SOTERM, Section 4.1); U will exist as U(IV) or U(VI) (Section 4.2); Np will speciate as Np(IV) or Np(V) (Section 4.3); Pu will exist as Pu(III) and Pu(IV) (Section 4.4); and Am will speciate as Am(III) (Section 4.5). Several actinide oxidation states will be unstable under the strongly reducing conditions expected in the repository. These include Np(VI), Pu(V), Pu(VI), and Am(V). Pu(V) and Pu(VI) could occur in isolated microenvironments in the repository, however, the DOE concludes that would not persist in significant quantities because diffusive transport through any brine present and (especially in the event of human intrusion) advective transport of brine would expose any oxidized Pu to reducing materials like metallic Fe from waste containers and Fe-based materials in the waste, Fe(II)-bearing solids produced by anoxic corrosion of metallic Fe, dissolved Fe(II) species, and metallic Al in the waste (Appendix SOTERM, Sections SOTERM-2 and SOTERM-4; Marcinowski 2001). Microbial activity, if it occurs, would also help create reducing conditions.

The DOE incorporated the uncertainties regarding the oxidation states of U and Pu in PA by assigning a probability of 0.5 that they will exist in the U(IV) and Pu(III) oxidation states, and a probability of 0.5 that these elements will speciate in the U(VI) and the Pu(IV) oxidation

1 *states (see also Appendix PA, Section SOTERM-5.2). The oxidation state for both elements is*
2 *selected by a single variable in the LHS. Therefore, in approximately half of the PA*
3 *realizations, the oxidation states of the transported actinides are Th(IV), U(IV), Pu(III), and*
4 *Am(III); and, in the other half of the realizations, the oxidation states are Th(IV), U(VI),*
5 *Pu(IV), and Am(III).*

6 *Laboratory studies with neodymium(III) (Nd(III)), Am(III), and Cm(III) were used to develop*
7 *a solubility model for the +III actinides, and this model was used to predict the solubilities of*
8 *Pu(III) and Am(III). Similarly, Th(IV) was used to develop a solubility model for the +IV*
9 *actinides, which was used for Th(IV), U(IV), Np(IV), and Pu(IV). Literature data for Np(V)*
10 *were used to develop a solubility model for the +V actinides, which was used only for Np(V).*
11 *The +V model was not used for other actinides because Pu(V) would not persist in significant*
12 *quantities in the WIPP. Using the oxidation-state analogy to extend the +III and +IV*
13 *solubility models to Pu(III) and to U(IV), Np(IV), and Pu(IV), respectively, is valid for these*
14 *reasons: First, the chemical behavior, especially the speciation and solubilities, of Nd(III),*
15 *Pu(III), Am(III), and Cm(III) is very similar. Second, the chemical behavior of Th(IV),*
16 *U(IV), Np(IV), and Pu(IV) is similar, although the solubility of Th(IV) is higher those of*
17 *U(IV), Np(IV), and especially Pu(IV). Third, Nd, Am, and Cm speciate only in the +III*
18 *oxidation state, and Th speciates only in the +IV oxidation state under typical laboratory*
19 *conditions, thus making experiments with these actinides much easier to carry out and*
20 *interpret than those with actinides that occur in more than one oxidation state, such as Pu.*

21 *The FMT calculations of actinide solubilities for the CRA-2004 PA featured the establishment*
22 *of equilibrium of Salado brine (GWB) or Castile brine (ERDA-6) with halite and anhydrite,*
23 *minerals present in large quantities in the Salado at the repository horizon. (These brines are*
24 *described in Appendix PA, Attachment SOTERM, Section SOTERM-2.2.1). The effects of the*
25 *MgO included the equilibrium of Salado brine or Castile brine with brucite and*
26 *hydromagnesite ($Mg_5(CO_3)_4(OH)_2 \cdot 4H_2O$) in the performance-assessment vectors with*
27 *microbial activity, and with brucite and calcite in the vectors without microbial activity (see*
28 *Appendix BARRIERS, Section 2; and Appendix PA, Attachment SOTERM). For the 1997*
29 *PAVT, it was assumed that Salado brine (Brine A) or Castile brine (ERDA-6) would be in*
30 *equilibrium with brucite and hydromagnesite ($Mg_5(CO_3)_4(OH)_2 \cdot 4H_2O$) in all of the*
31 *performance-assessment vectors (both with and without microbial activity) (EPA 1998a,*
32 *1998b). For the CCA, equilibria among Salado brine (Brine A) and Castile brine (ERDA-6)*
33 *and brucite and magnesite were assumed (CCA Appendix BACK).*

34 *The FMT calculations for the CRA-2004 PA also included the effects of acetate, citrate,*
35 *EDTA, and oxalate on the speciation and solubilities of the +III, +IV, and +V actinides (see*
36 *Appendix PA, Attachment SOTERM). The FMT calculations for the CCA PA and the 1997*
37 *PAVT did not include organic ligands.*

38 *Table 6-13 provides the solubilities calculated for the +III, +IV, and +V actinides and*
39 *estimated for the +VI oxidation state for the CRA-2004 PA, and compares them to the*
40 *solubilities calculated or estimated for the CCA PA and the 1997 PAVT. An uncertainty range*
41 *of +1.4 orders of magnitude and -2.0 orders of magnitude was applied to the FMT predictions*
42 *for the CRA-2004 PA (see Appendix PA, Attachment SOTERM, Section SOTERM-3.6). This*

⁴ Hobart and Moore (1996).

is the same uncertainty range used for the CCA PA and the 1997 PAVT. LHS was used to sample solubilities from these ranges.

A thermodynamic speciation and solubility model was not developed for U(VI); instead, literature data estimated the solubilities of U(VI) in the repository (Appendix PA, Attachment SOTERM, Section SOTERM-3.0; based on Hobart and Moore [1996]). These estimates have not been used for other actinides in the repository because Np and Pu will not persist in significant quantities in the +VI oxidation state.

~~Actinide concentration may not be equal to the values sampled in LHS. This condition could arise when there are not sufficient actinides in the solid phase in a particular cell, when combined with the dissolved actinides that may have been transported into that cell from an adjacent cell, to achieve the concentration value as determined by LHS sampling. This situation is referred to as inventory limited.~~

The actinide inventory is depleted on a cell-by-cell basis by the computer code NUTS (NUclide Transport Systems) for the undisturbed, E1, and E2 scenarios. The treatment of the E1E2 scenario is described in Section 6.4.13.5. In a computational cell, the processes affecting actinide dissolved *actinide* concentrations are dissolution of solid actinide compounds, advection of dissolved actinides by brine flow from neighboring cells, and interaction with colloidal particles (see Section 6.4.3.6). NUTS dissolves each actinide until the maximum concentration determined by the actinide-source-term algorithms is obtained or an inventory limit is reached. In the repository, the transfer of actinides between solid phases and solution is tracked to preserve mass balance of the actinide inventory. Outside the repository, the model does not

1 precipitate actinides into the solid phase, thereby giving a conservative measure of mobile
2 actinide quantities *concentrations* (see Appendix *PA, Attachment SCR, Section SCR.2.5.3.2*
3 *FEP W59*).

4 *See Appendix PA, Attachment SOTERM, Section SOTERM-7.0, for a detailed description of*
5 *the implementation of the actinide source term in PA.*

6 6.4.3.6 Source Term for Colloidal Actinides

7 Colloidal actinides are discussed in greater detail in Appendix *PA, Attachment SOTERM*
8 ~~(Section SOTERM-6)~~. Colloidal particles form in the repository by *through* a variety of
9 processes, including waste degradation, microbial activity, rock decomposition, and chemical
10 condensation. These particles may also be carried into the repository by liquids moving from the
11 Salado or through boreholes. Because of the presence of soils, nutrients, and cellulosic
12 substrates for microbial action in WIPP waste (see Appendix *TRU WASTE BIR*), humic
13 substances and microbes will be present in disposal room brines, or may form in situ. Actinide-
14 intrinsic colloids may form in the disposal rooms from condensation of dissolved actinides.
15 Mineral fragments, as well as humic substances and microbes, may provide surfaces on which
16 dissolved actinides may *could* sorb.

17 Four types of colloidal particles are believed to cover the range of possible behavior of all colloid
18 types (see Appendix *PA, Attachment SOTERM, Section SOTERM.6.1.2*). The four particle
19 types considered in performance assessment *PA* are microbes, humic and fulvic acids (humic
20 substances), actinide-intrinsic (intrinsic), and mineral fragments. The concentration of actinides
21 carried by each colloidal particle type depends on many of the same chemical conditions that
22 govern the concentration of dissolved actinides.

23 Actinide concentrations associated with humic substances and microbes are linked to dissolved
24 actinide concentrations through proportionality constants based on experimental results. For
25 humic substances, actinide complexation constants from WIPP-specific experiments or from
26 published literature are coupled with experimentally determined site-binding densities and
27 solubilities of different types of humic substances in WIPP brines. For microbes, actinide uptake
28 was experimentally determined through experiments with WIPP-relevant bacteria cultures.
29 Actinide concentrations associated with mineral fragment-type colloidal particles are ~~estimated~~
30 based on results from experiments designed to determine mobile concentrations in brines,
31 coupled with site-binding densities of mineral substrates. For the ~~Pu(IV) polymer~~
32 *plutonium(IV) polymer*, actinide concentrations are determined through solubility experiments
33 conducted from over- and undersaturation over a range of *undersaturated ranges of* pmH
34 values. Intrinsic colloids of other actinides were determined to be of negligible importance and
35 are eliminated from performance assessment *PA* calculations. For more discussion on this topic,
36 refer to Appendix *PA, Attachment SOTERM (Section SOTERM.6.3.2.2)*.

37 Actinides associated with microbes and humics are related to the concentration of dissolved
38 actinides in the repository through proportionality constants determined from interpretation of
39 WIPP-relevant experiments and the literature (Appendix *PA, Attachment SOTERM, Sections*
40 ~~SOTERM.6.3.3 and SOTERM.6.3.4~~). The proportionality-constant relationship is not based
41 ~~rigorously~~ on thermodynamic equilibrium but is simply an empirical relationship. The

1 concentration of actinides associated with the ~~Pu(IV) polymer~~ *plutonium(IV) polymer* is a
 2 constant value determined from experimental results at the pmH conditions dictated by the
 3 presence of ~~the MgO backfill~~ *engineered barrier*. Likewise, the concentration of actinides
 4 associated with mineral colloids is also a constant value, not linked to the concentration of
 5 dissolved actinides. Actinides associated with humics and microbes represent most of the
 6 colloidal actinide source term. Consequently, the colloidal actinide source term is closely related
 7 to the dissolved actinide source term. As discussed in Section 6.4.6.2, however, the source terms
 8 are considered separately for transport in the Culebra.

9 For ~~performance assessment~~ *PA*, the concentration of each actinide element on each colloidal
 10 particle type during a realization is a fixed value. The concentration parameters are summarized
 11 in ~~Table 6-12~~ *Table 6-14*. Actual values of actinide concentrations on colloidal particles are
 12 constrained by inventory limits.

13 The concentrations of colloidal actinides indicated in this section are assumed to be
 14 ~~concentrations of actinides mobilized on colloidal particles~~. The indicated concentrations will be
 15 entrained in moving brine. For conservatism, it is assumed that no actinides sorb onto colloidal
 16 particles that are not mobile in the repository. Thus, all actinides in the repository will be present
 17 in the solid phase, dissolved in the aqueous phase, or ~~as~~ colloidal actinides suspended in the
 18 aqueous phase.

19 When actinide inventory in a model cell is sufficient, the concentration of colloidal actinides will
 20 be at the values indicated in ~~Table 6-12~~ *Table 6-14*. The total concentration of an actinide in
 21 solution and suspension is limited by the amount of solids available to ~~dissolve~~ from the
 22 inventory. This condition is called “inventory-limited.” ~~when it occurs~~.

23 Colloid concentrations are calculated by the source-term procedure described in Appendix *PA*,
 24 *Section SOTERM-4.3.2*. ~~SOTERM (Sections SOTERM.7.1.4 and SOTERM.7.2)~~. Processes
 25 affecting the transport of colloids in the Culebra are addressed in Section 6.4.6.2.2.

26 **6.4.4 Shafts and Shaft Seals**

27 The four shafts connecting the repository to the surface are represented in ~~performance~~
 28 ~~assessment~~ *PA* with a single shaft, represented by *two primary regions above the repository*,
 29 ~~Regions 2 through 11~~ *and a concrete monolith* on (Figures 6-14 and 6-15). This single shaft has
 30 a cross section and volume equal to the total cross section and volume of the four real shafts it
 31 represents and is separated from the waste disposal regions ~~in the model~~ by the true north-south
 32 distance from the waste to the nearest shaft (the Waste Shaft). Upon closure of the repository,
 33 the shafts will be sealed as described in Section 3.3.1. The seal system *was originally* is
 34 represented in *the CCA PA* by discretizing 11 *discrete* modeled regions in the shaft. *The*
 35 *representation was simplified by modeling the behavior of these 11 regions with two primary*
 36 *regions (Upper Shaft and Lower Shaft in Figures 6-14 and 6-15) that have properties*
 37 *simulating the behavior of the original 11 regions (see Appendix PA, Section PA-4.2.7). An*
 38 *analysis of the CCA results concluded that no significant flow of gas or brine would occur*
 39 *within the shaft seal system over the 10,000-year regulatory period. The new shaft model*
 40 *underwent peer review as required by 40 CFR § 194.27 and was incorporated in BRAGFLO*
 41 *(see Appendix PA, Section PA-4.2.7; Section 9.3.1.3.4; and Appendix PEER). The current*

^{a 1} In units of moles colloidal actinide per liter

^{b 2} In units of moles colloidal actinide per mole dissolved actinide

^{e 3} In units of moles total mobile actinide per liter

^{d 4} A cumulative distribution from 0.065 to 1.60 with a mean value of 1.1 was used.

^{e 5} *Microbial colloids are not included in futures that do not have without microbial gas generation.*

NOTE: The colloidal source term is added to the dissolved source term to arrive at a total source term. Mineral fragments were provided with distributions, but the maximum was used as described in Appendix PA, Attachment SOTERM (Section SOTERM.7.1.3). Humic proportionality constants for III, IV, and V were provided with distributions, but only the Castile Am(III) and Pu(III) were sampled.

2 *model divides the shaft into an upper region with all elements above the Salado and a lower*
 3 *region with all Salado elements. These regions are assigned material property distributions*
 4 *that represent the combined properties of all the individual materials in series.* These regions
 5 are as follows: an earthen fill region above the Rustler; a compacted clay column in the Rustler;
 6 an asphalt region at the top of the Salado; three concrete sections within the Salado; an upper
 7 Salado compacted clay column; a thick section of compacted crushed salt; a lower Salado
 8 compacted clay column separated into upper and lower segments; and a concrete monolith at the
 9 repository horizon (see Appendix SEAL, Section 4 and Appendix A). The concrete components
 10 in the Salado represent the concrete asphalt waterstops in the seal system design. Seal material
 11 parameter values used in the PA are provided in *Table 6-15* Table 6-13.

12 Conceptually, the shafts are assumed to be surrounded by a DRZ in the Salado. Within the
 13 bedded halite, the DRZ begins to form immediately after excavation and develops progressively
 14 as a function of *from* unloading as the formation creeps toward the excavated area. From a
 15 sealing perspective, the most important characteristic of the DRZ is the higher permeability that
 16 results from dilatant deformation and the increased pore volume.

17 The properties of the DRZ are known to vary with the type of adjacent material, time, and depth.
 18 When the shaft seals are emplaced, back pressures will progressively develop *over time* as the
 19 surrounding salt creeps inward. The back pressure applied by the seal material will
 20 progressively reduce the magnitude of the stress differential, which is the source for the DRZ
 21 microfracturing mechanism. The back pressure also results in a higher mean stress, which
 22 induces *of the* DRZ healing. The shaft DRZ permeability will, over time, approach that of the

1 intact halite. Also, since the creep rate of the salt surrounding the shafts depends on depth, the
2 back pressures supplied by the seal materials will result in DRZ healing at rates that increase
3 with depth. The relative stiffness of the seal material is a factor, as well.

4 ~~In the performance assessment model, the radial extent of the DRZ around the shaft seal~~
5 ~~materials is an input parameter obtained by numerical model calculations and is corroborated by~~
6 ~~field data (see Appendix SEAL, Section 8 and SEAL Appendix C). The permeability of the~~
7 ~~DRZ around the shaft versus distance is assumed to follow a log-linear relationship.~~
8 ~~Permeability of the DRZ at the shaft wall is based on experimental data collected in the air intake~~
9 ~~shaft (Dale and Hurtado 1996) and Room M (Van Pelt 1995). More information on how the~~
10 ~~DRZ is incorporated into the shaft parameters is contained in Appendix PAR (Parameter 12).~~

11 The DRZ surrounding the shaft is not *explicitly* represented ~~explicitly~~ in the BRAGFLO mesh
12 (Figures ~~6-13 to 6-15~~ *6-14 and 6-15*). Rather, the mesh ~~has been~~ *was* simplified to represent only
13 the cross-sectional area of the four WIPP shafts, and the permeability values ~~for~~ *of* the various
14 seal components at different times have been adjusted (*in the parameter database*) to account for
15 the presence of the shaft DRZ. This adjustment, which yields effective permeabilities, can be
16 done because in Darcy flow, the flux through a porous medium is a linear function of the product
17 ~~of the permeability of the medium~~ *of the permeability* and the cross-sectional area across which
18 flow occurs. Thus, the flux that would occur through a shaft and its surrounding DRZ can be
19 modeled equivalently using the shaft cross-sectional area with a higher seal component
20 permeability. Equations for the derivation of the effective permeabilities are given in *Appendix*
21 *PA, Appendix Attachment PAR (Parameters 64 and 65), 12)* and Appendix IRES (Section
22 IRES.2). ~~The permeabilities of shaft components are calculated in the SCMS (see Section 6.4.11)~~
23 ~~from LHS parameter values according to these equations. Appendix IRES (Section IRES.2)~~
24 ~~shows calculated shaft component effective permeabilities.~~

25 **6.4.5 The Salado**

26 The Salado is the principal natural barrier to fluid flow between the waste disposal panels and the
27 accessible environment. Fluid flow in *the Salado under* natural (*undisturbed*) conditions ~~in the~~
28 ~~Salado~~ is discussed in Section 2.2.1.3. ~~Excavation of the r~~Repository *excavation* has altered
29 natural pressure gradients in the Salado, creating the potential for fluid flow into the excavation.
30 Fluid flow, gas generation, and volume changes from creep closure ~~cause changes~~ *alter the* ~~in~~
31 pressure gradients through time. Salt creep, as well as possible fracturing from high repository
32 pressure, alters the permeability and other flow properties of the rock near the repository.
33 Depending on pressure gradients ~~developed~~ and altered material properties, gas and brine flow
34 may be enhanced in affected portions of the Salado.

35 For performance assessment *PA*, the DOE conceptualizes the Salado as a porous medium
36 composed of several rock types arranged in layers, through which flow occurs according to
37 Darcy's law. Two rock types, impure halite and anhydrite, are used to represent the intact
38 Salado. Once sampled, model parameters for all layers are uniform and constant, with two
39 exceptions: porosity and permeability. ~~Conceptually, this~~ *The* assumption of constant properties
40 is based on observations of *observed* compositional and structural regularity in layers exposed by
41 the repository and on the inference that there is *inferred small* little variation in large-scale
42 averages of rock or flow properties across the disposal system. For several meters above and

Effective Porosity (percent)	—	—	32.0
Pore Volume Compressibility (1/pascals)	—	—	3.1×10^{-8}

^{a1} Capillary pressure for all shaft materials is set to 0.

^{a2} These values represent the permeabilities of the seal material ~~without incorporating~~ the surrounding DRZ ~~incorporated~~. See Appendix IRES, Section IRES.2, for time dependent values.

1 below the repository, a DRZ has increased *higher* permeability compared to *than* intact rock and
 2 offers little resistance to flow between anhydrite interbeds and the repository. ~~In all rock units,~~
 3 ~~p~~Porosity can vary from *its* initial values due to *pressure-dependent* compressibility, ~~depending~~
 4 ~~on pressure changes in a computational grid block~~. As discussed in Section 6.4.5.2, a model has
 5 been implemented in interbeds to simulate the effects of fracturing caused by high repository
 6 pressure as pore pressure approaches or exceeds lithostatic.

7 Specific information about the three submodels used to represent impure halite, Salado interbeds,
 8 and the DRZ is presented in the following sections.

9 6.4.5.1 Impure Halite

10 The ~~DOE~~*PA* uses a single porous medium with spatially constant rock and hydrologic properties
 11 (*labeled “Salado”* Region 19 in Figures 6-13 and 6-146-14 and 6-15) in performance
 12 ~~assessment~~*PA* to represent intact, halite-rich layers in the Salado and minor interbeds contained
 13 within ~~those~~ layers that are not explicitly represented. A comparison ~~has been~~ *was* made
 14 between the simplified stratigraphy used in the ~~performance assessment~~*PA* model and a model
 15 with a more detailed stratigraphy in the vicinity of the repository; ~~†~~*This* comparison supports use
 16 of the stratigraphic representation used for ~~performance assessment~~*PA*. This model comparison
 17 is described in Christian-Frear and Webb (1996).

18 Gas may not be able to flow through intact, halite-rich strata of the Salado under realistic
 19 conditions for the repository. Gas flow in liquid-saturated rock depends on the gas pressure

1 required to overcome capillary resistance to initial gas penetration and development of
 2 interconnected gas pathways that allow gas flow (threshold pressure). While the permeability of
 3 halite is known to be low, its threshold pressure has never been measured. An empirical
 4 relationship between threshold pressure and permeability in non-WIPP rocks (Davies 1991, 17-
 5 19) suggests that threshold pressure will be sufficiently high *enough* that gas will not be *unable*
 6 to flow through the halite-rich strata of the Salado under any conditions foreseeable for the WIPP
 7 (see Appendix *PA, Attachment* MASS, Section MASS-13.1). *The DOE* \forall values used by the
 8 DOE for halite threshold pressure are consistent for generic material of low permeability and
 9 prevent the flow of gas *flow* into the impure halite regions (*Table 6-16* ~~Table 6-14~~). This is a
 10 conservative assumption because gas flow in halite would decrease the pressure in the repository
 11 and the driving force available for flow elsewhere. *Table 6-16* ~~Table 6-14~~ shows various
 12 parameter values used in modeling the Salado impure halite. Additional information on
 13 parameter values is contained in Appendix *PA, Attachment* PAR (Parameters 17 through 19 and
 14 Table *PAR-2* ~~PAR-32~~).

15 **Table 6-16-14. Salado Impure Halite Parameter Values**

Parameter (units) ^{a 1}	Maximum	Minimum	Median or Constant
Permeability (square meters)	10 ⁻²¹	10 ⁻²⁴	3.16 × 10 ⁻²³
Effective Porosity (percent)	3.0	0.10	1.0
Threshold Pressure, P _t (pascals) ^{b 2}	1.13 × 10 ⁸	1.03 × 10 ⁷	3.41 × 10 ⁷
Residual Brine Saturation, S _{br} (unitless)	<i>0.60</i>	<i>0</i>	0.3
Residual Gas Saturation, S _{gr} (unitless)	<i>0.40</i>	<i>0</i>	0.2
Pore Distribution Parameter, λ (unitless)	<i>1.0</i>	<i>0.20</i>	0.7
Maximum Capillary Pressure (pascals)	–	–	10 ⁸
Rock Compressibility (1/pascals) ^{e 3}	1.92 × 10 ⁻¹⁰	2.94 × 10 ⁻¹²	9.75 × 10 ⁻¹¹

^{a 1} See *Table 6-11* ~~Table 6-9~~ for fluid properties.

^{b 2} Threshold pressure (P_t) determined from the relationship: P_t = PCT_A · k^{PCT_EXP} where PCT_A and PCT_EXP are constants and k is the permeability.

^{e 3} Pore compressibility = rock compressibility/effective porosity.

16 **6.4.5.2 Salado Interbeds**

17 Three distinct anhydrite interbeds are modeled in BRAGFLO, representing MB138 (*see*
 18 *Region 20* in Figures 6-13 and 6-14 ~~6-14 and 6-15~~), anhydrite layers a and b (*Anhydrite*
 19 *AB*) (*Region 21*), and MB139 (*Region 28*). The three *intact* interbeds have the same set of model
 20 parameters, and the parameters are initially spatially constant. Porosity and permeability can
 21 vary spatially during a simulation, depending on the extent of interbed fracturing. The interbeds
 22 differ only in position and thickness.

23 The three interbeds explicitly represented in the BRAGFLO model are included because they
 24 exist in the disturbed region, as modeled around the repository within which fluid is expected to
 25 be able to flow with relative ease compared to the surrounding formation. MB139 and anhydrite
 26 layers a and b are present within the DRZ that forms around excavations, *as shown by Park and*
 27 *Holland (2003) in their analysis of the effects of raising the repository horizon 2.34 meters*

1 *(7.67 feet)*. MB138 is included along with a thick DRZ because of uncertainty in the extent and
 2 properties of the DRZ and the associated long-term isolation of MB138 from the repository. *A*
 3 *more detailed examination of the DRZ was necessary to incorporate the Option D panel*
 4 *closure into the PA grid. Even though the DRZ would not reach MB 138, PA models the*
 5 *potential for a hydraulic connection between MB 138 and the repository through the DRZ.*

6 In BRAGFLO, brine flows between the Salado and the repository in response to fluid potential
 7 gradients that may form over time. Because of the ~~low permeability of the impure halite's~~ *low*
 8 *permeability* and relatively small surface area ~~involved~~, direct brine flow between the impure
 9 halite and the repository is relatively small. The interbeds included in the BRAGFLO model of
 10 the Salado, (~~Regions 20, 21, and 28~~) however, can serve as conduits for brine flow between the
 11 impure halite and the repository. Conceptually, brine flows laterally along higher permeability
 12 interbeds towards or away from the repository and vertically between the interbeds and the lower
 13 permeability halite. Because the interbeds have a very large contact area with adjacent halite-
 14 rich rock, even a very small flux from the halite into the interbeds (for brine inflow) or to the
 15 halite from the interbeds (for brine outflow) can accumulate ~~into a significant quantity~~ *quantities*
 16 of brine. In this manner, halite serves as a source or sink for brine in the repository. It is
 17 expected that, because of density differences between gas and brine and their stratification within
 18 the repository, brine outflow will be *predominantly* in MB139, and gas outflow will occur in
 19 anhydrite a and b or MB138. However, the model does not preclude other flow patterns.

20 Interbeds contain natural fractures that may be partially healed, *but anhydrite lithologies*
 21 *proximal to disposal rooms will be highly distorted as the rooms creep closed. Fractured and*
 22 *distorted anhydrite would not be expected to heal in a manner expected of the DRZ in salt.* If
 23 high pressure is developed in an interbed, its preexisting fractures may dilate or new fractures
 24 may form, altering its porosity and permeability. Pressure-dependent changes in permeability
 25 are supported by experiments conducted in the WIPP ~~underground~~ and in the laboratory
 26 (Beauheim et al. 1993). Accordingly, the DOE has implemented in BRAGFLO a porous-media
 27 model of interbed dilation and fracturing that causes the porosity and permeability of *an*
 28 *interbed's* computational cell ~~in an interbed~~ to increase as its pore pressure rises above a
 29 threshold value. Model details are presented in Appendix *PA, Section PA-4.2 and Attachment*
 30 *MASS, Section MASS-13.0*. BRAGFLO (~~Section 4.10~~) and Appendix ~~MASS (Section~~
 31 ~~MASS.13.3)~~). To the extent that it occurs, *interbed* dilation or fracturing of interbeds is
 32 expected to increase the transmissivity of interbed intervals. The threshold pressure of dilated or
 33 fractured interbeds is expected to be low because apertures of the fractures increase; thus, fluid is
 34 expected to ~~be able to~~ flow outward readily if adequate pressure is ~~available to~~ dilates the
 35 interbeds.

36 The model used to simulate the effects of interbed dilation or fracturing is explained in detail in
 37 Appendix ~~BRAGFLO (Section 4.10)~~ *PA, Attachment MASS, Section MASS-13.0*. In summary,
 38 it assigns a fracture initiation pressure above the initial pressure at which local fracturing takes
 39 place, ~~and e~~ Changes in permeability and porosity occur above this pressure. Below this fracture
 40 initiation pressure, an interbed has the permeability and compressibility assigned by LHS ~~and~~
 41 ~~representative of~~ *to represent* intact rock. Below the fracture initiation pressure, the initial
 42 sampled porosity is modified slightly with pressure caused by compressibility. Above the
 43 fracture initiation pressure, the local compressibility of the interbed is assumed to increase
 44 linearly with pressure. This greatly increases the rate at which porosity increases with increasing

1 pore pressure. Additionally, permeability increases by a power function of the ratio of altered
 2 porosity to initial porosity. For numerical reasons (that is, to prevent unbounded changes in
 3 parameter values that would create numerical instabilities in codes), a pressure is specified above
 4 which porosity and permeability change no further.

5 Parameters associated with the interbeds are shown in ~~Table 6-17~~ **Table 6-15**. ~~Table 6-18~~ **Table**
 6 ~~6-16~~ lists parameters used in the **to** model of interbed dilation and fracture. Additional
 7 information about interbed parameters is included in **Appendix PA, Appendix Attachment PAR,**
 8 (Table 2, ~~PAR 36~~ and Parameters 20 through 25).

9 **Table 6-17-15. Parameter Values for Salado Anhydrite Interbeds a and b, and MB138**
 10 **and MB139**

Parameter (units) ^{a, 1}	Maximum	Minimum	Median or Constant
Permeability (square meters)	7.94×10^{-18}	10^{-21}	1.29×10^{-19}
Effective Porosity (percent)	1.7 –	0.60 –	1.1
Threshold Pressure, P _t (pascals) ^{b, 2}	5.28×10^6	2.32×10^5	9.74×10^5
Residual Brine Saturation, S _{br} (unitless)	0.174	0.007846	0.084
Residual Gas Saturation, S _{gr} (unitless)	0.197	0.014	0.077
Pore Distribution Parameter, λ (unitless)	0.842	0.491	0.644
Maximum Capillary Pressure (pascals)	–	–	10 ⁸
Rock Compressibility (1/pascals) ^{c, 3}	2.75×10^{-10}	1.09×10^{-11}	8.26×10^{-11}
Brine Far Field Pore Pressure at elevation of MB139 and shaft intersection (pascals)	13.9 × 106	11.0 × 106	12.5 × 106

^{a, 1} See ~~Table 6-11~~ Table 6-9 for fluid properties.

^{b, 2} Threshold pressure (P_t) determined from the relationship: P_t = PCT_A · k^{PCT_EXP} where PCT_A and PCT_EXP are constants and k is the permeability.

^{c, 3} Pore compressibility = Rock compressibility/effective porosity.

11 **Table 6-18-16. Fracture Parameter Values for Salado Anhydrite Interbeds a and b, and**
 12 **MB138 and MB139**

Parameter (units)	Constant
Fracture initiation pressure at MB139, base of shaft (pascals)	12.7×10^6
Increment to give full fracture porosity (percent), MB139 and MB138 ^{a, 1}	3.9
Increment to give full fracture porosity (percent), Anhydrite a and b ^{a, 1}	23.9
Full fracture permeability (square meters)	10 ⁻⁹
Increment above fracture initiation pressure to obtain full fracture pressure (pascals) ^{a, 1}	3.8×10^6

^{a, 1} A fitting parameter to yield desired dilation over a variation in pressure.

13 6.4.5.3 DRZ

14 In the DRZ (*see* ~~Region 22 in~~ Figures 6-136-14 and 6-146-15) near the repository, permeability
 15 and porosity are expected to generally increase in both halite and interbeds. These increases are

1 due to a variety of processes. Creep closure and stress-field alterations as the result of the
 2 excavation are the dominant causes, similar to the processes discussed for the formation of
 3 **forming** the DRZ around the shaft (see Section 6.4.4). The increases in permeability and
 4 porosity in interbeds are not ~~expected~~ **likely** to be completely reversible with creep closure of the
 5 disposal rooms. The increase in DRZ permeability increases the ability of fluid to flow from
 6 interbeds to the waste disposal region. The increase in DRZ porosity provides a volume in
 7 which some fluid could be retained so that it does not contact waste or slows actinide movement.

8 ~~Performance assessment~~ **In approximating** approximates the effects of the DRZ, ~~performance~~
 9 ~~assessment~~ **PA** conservatively **overestimates** with respect to brine flow **toward** the repository (see
 10 Appendix **PA, Attachment MASS, Section MASS 13.13.4**). In the model, the permeability of
 11 this region is increased relative to intact Salado rock for the duration of a realization. The
 12 porosity of the modeled DRZ is increased by a fixed value of 0.0029 (0.29 percent) above the
 13 sampled **porosity of the** intact Salado impure halite. The modeled DRZ extends above and
 14 below the repository from the base of MB138 to MB139, **thereby retaining the geometry used in**
 15 **the CCA and 1997 PAVT**. The ~~performance assessment~~ **PA** treatment of the DRZ creates a
 16 permanent high permeability region that **may allow fluid** does not significantly impede flow
 17 between the repository and affected interbeds. ~~Table 6-17~~ **Table 6-17** shows parameter values
 18 used in the ~~performance assessment~~ **PA** representation of the DRZ.

19 **Table 6-196-17. DRZ Parameter Values**

Parameter (units) ^{a 1}	Maximum	Minimum	Median or Constant
Permeability (square meters)	3.16×10^{-13} –	3.98×10^{-20} –	10^{-16} 10^{-15}
Effective porosity (percent) ^{b 2}	3.3 –	0.04	1.29
Threshold pressure, P _t (pascals)	–	–	0
Residual brine saturation, S _{br} (unitless)	–	–	0
Residual gas saturation, S _{gr} (unitless)	–	–	0
Pore distribution parameter, λ (unitless)	–	–	0.7
Maximum capillary pressure (pascals)	–	–	10 ⁸
Rock compressibility (1/pascals) ^{e 3}	–	–	7.41×10^{-10}

^{a 1} See ~~Table 6-11~~ **Table 6-9** for fluid properties.

^{b 2} The DRZ effective porosity value for each realization is equivalent to the sampled value for the Salado halite plus 0.0029 (0.0029 is the difference between the medians for the DRZ and the halite).

^{e 3} Pore compressibility = rock compressibility/effective porosity.

20 **The DOE originally used a constant permeability for the DRZ over the 10,000-year regulatory**
 21 **time frame. However, the EPA required the DOE to treat the DRZ permeability as uncertain**
 22 **during the PAVT (EPA 1998, TSD V-B-14). The range is sampled to determine a fixed value**
 23 **for each realization over the 10,000-year period. Additionally, in the 1997 PAVT, the**
 24 **anhydrite fracture model was applied to the DRZ to capture the effects of halite fracture under**
 25 **high repository pressures. As was done in the 1997 PAVT, the CRA-2004 PA treats the DRZ**
 26 **permeability as an uncertain parameter, and the anhydrite fracture model is also applied to**
 27 **the DRZ. The parameter values are shown in Table 6-19.**
